

Polychromatophilic erythroblast

In the basophilic erythroblast stage, the cell began to synthesize **hemoglobin**. Its **accumulation** changes the tint properties so that the polychromatophilic erythroblast is both **eosinophilic** (acidophilic) due to hemoglobin and **basophilic** due to ribosomes in the cytoplasm. The resulting color of the cytoplasm is thus a combination of both colors or eosinophilic and basophilic regions are visible in them. The nucleus is again **smaller** and **more condensed** compared to the previous stage.
