

# DNA Replication

## Under construction / Forgotten

**This article was marked by its author as *Under construction*, but the last edit is older than 30 days.** If you want to edit this page, please try to contact its author first (you will find him in the history ([https://www.wikilectures.eu/index.php?title=DNA\\_Replication&action=history](https://www.wikilectures.eu/index.php?title=DNA_Replication&action=history))). Watch the page as well. If the author will not continue in work, remove the template {{Under construction}} and the page.

Last update: Monday, 08 Dec 2014 at 5.44 pm.

**DNA replication** produces two new daughter DNA strands that are identical to the original DNA. The resulting DNA strands are semi-conservative, as they contain one strand from the original DNA molecule and one newly synthesized strand. The process requires DNA helicase to unwind the DNA double helix. DNA single-stranded binding proteins (SSBPs) bind to single stranded regions of DNA and help stabilize the extended single stranded templates<sup>[1]</sup>. DNA gyrase catalyses negative supercoils and assist the unwinding process.

## Leading strand

New DNA strands are initiated by RNA primers, the synthesis of which is catalyzed by enzymes called primases. In the 5'-3' direction a continuous strand of DNA is created, the leading strand.

## Lagging strand

Okazaki fragments are created leading to the formation of the lagging strand. Short segments are covalently bound together by polynucleotide ligase.

## Y-replication fork

DNA replication takes place at multiple points and forms replication forks which, are Y shaped structures. The process progresses in both directions forming replication bubbles. The replication origins are approximately 50 to 300 kb (kilobases) apart<sup>[2]</sup>. After initiation, elongation of the DNA is carried out by DNA polymerase III. Polymerase I subsequently removes RNA primers.
