

Spongiosis (dermatopathology)

Spongiosis is a dermatopathological descriptive term for intercellular edema in the epidermis. Owing to the edema, the keratinocytes are separated by clearly distinct spaces, which, according to some authors, give the epidermis a spongy appearance. Inflammatory infiltrate (exocytosis) may be present depending on the specific disease and its stage, but its presence is not necessary. Spongiosis can occur in the following dermatitis:

- acute and subacute dermatitis:
- allergic contact dermatitis,
 - irritative contact dermatitis,
 - endogenous eczemas (atopic eczema, dermatitis dyshidrotica, Eczema nummulare),
- chronic dermatitis:
 - lichen simplex chronicus,
 - pityriasis rosea,
 - dermatophytoses,
 - lichen striatus,
 - stasis dermatitis.

Mild spongiosis (spongiotic dermatitis).
